Abstract

The objective of this paper was to evaluate a recently proposed comprehensive model for three-dimensional single-ring infiltration and its suitability for estimating soil hydraulic properties. Infiltration data from four different soils with contrasting characteristics were inverted to estimate field-saturated soil hydraulic conductivity, K_{fs} , values using a total of fourteen different scenarios. Those scenarios differed by: i) the way they constrained the macroscopic capillary length, λ , and the initial and saturated soil water contents, θ_i and θ_s , ii) the use of transient or steady-state data, and iii) the fitting methods applied to transient data. For comparative purposes, the SSBI method (Steady version of the Simplified method based on a Beerkan Infiltration run) was also applied. For validation purposes K_{fs} data estimated from the different scenarios were compared with those values obtained by numerical inverse modeling with HYDRUS-2D/3D. This comparison identified Approaches 1 and 3, which respectively estimate K_{fs} via optimization and using analytical expressions, as the most accurate methods. The steady-state scenario of Approach 4 and the SSBI method, both of which use a λ value of first approximation, appeared preferable for field campaigns aimed to sample remote or large areas, given that they do not need additional data and still provide acceptable estimates. The reliability of K_{fs} data was also checked through a comparison with unsaturated hydraulic conductivity, K_h , values measured in laboratory on extracted soil cores, in order to discriminate between theoretically possible ($K_{fs} > K_h$) and impossible ($K_{fs} \leq K_h$) situations. Physically possible K_{fs} values were always obtained with the exception of the crusted soil, where $K_{fs} < K_h$ situations suggested that the crust layer reduced water flow during ponding experiments in the

31 field. The new comprehensive model tested in this study represents a valuable tool for analyzing
32 both transient and steady-state infiltration data, as well as experiments carried out with different
33 depths of ponded water, ring sizes and ring insertion depths.

34 **Keywords:** infiltration model, single-ring infiltrometer, Beerkan, hydraulic conductivity.

35 1. Introduction

36 Knowledge of soil properties is essential for modeling hydrological processes. Among other
37 properties, the field-saturated soil hydraulic conductivity, K_{fs} , has an important role in the
38 partitioning of rainfall into runoff and infiltration (Dusek et al., 2012). Different devices and
39 techniques have been developed over time to measure K_{fs} in the field, such as the Guelph
40 permeameter, the double- and the single-ring infiltrometers, among others (Angulo-Jaramillo et al.,
41 2016). The Guelph permeameter is a device that establishes three-dimensional, constant-head
42 infiltration within a small well excavated into the soil (Reynolds and Elrick, 1985). The double-ring
43 infiltrometer uses two concentric rings, namely an inner ring and a buffering ring, to create a one-
44 dimensional (1D) infiltration process under the inner ring (Reynolds et al., 2002). However, some
45 limitations may be encountered in the field when applying these methods. When using the Guelph
46 permeameter, the excavation of the well may cause soil compaction, artificially decreasing the
47 infiltration rates (Bagarello et al., 1999). The water flow under the inner ring of the double-ring
48 infiltrometer rarely approaches a one-dimensional infiltration process in practice (Reynolds et al.,
49 2002). Moreover, this latter method also requires a large amount of water to maintain ponding
50 conditions inside the buffering ring, thus limiting its application in remote areas.

51 The single-ring infiltrometer technique (Reynolds and Elrick, 1990) is a widespread method
52 (e.g., Braud et al., 2017), which has the advantage of speed and simplicity over more cumbersome
53 procedures, such as the Guelph permeameter and the double-ring infiltrometer. With a single-ring
54 infiltrometer, a constant or falling-head infiltration process has to be established. Different methods

for calculating K_{fs} from single-ring data have been developed over time. Among them, the one-ponding depth method by Reynolds and Elrick (1990) and the similar method by Wu et al. (1999) both estimate K_{fs} from steady-state single-ring infiltrometer data. Other approaches make use of transient infiltration data (e.g., Wu et al., 1999; Wu and Pan, 1997) to determine K_{fs} . These alternative approaches may alleviate the experimental efforts needed to determine K_{fs} data in the field (Di Prima et al., 2018b). For instance, limiting the analysis to the transient phase may prove advantageous when characterizing low permeability soils, by reducing the required measurement time (Bagarello et al., 2014c).

A variation of the single-ring infiltrometer technique is the Beerkan experiment, which consists of infiltrating water through a ring inserted shallowly (e.g., 1 cm) into the soil with a quasi-zero head of water imposed on the soil surface (Braud et al., 2005). Many different methods have been used to interpret Beerkan data. As an example, the Beerkan Estimation of Soil Transfer parameters (BEST) methods (Bagarello et al., 2014b; Lassabatere et al., 2006; Yilmaz et al., 2010) enable the user to derive the whole set of soil hydraulic parameters related to water retention and unsaturated hydraulic conductivity curves. Bagarello et al (2014c) and Bagarello et al. (2017) proposed the TSBI and SSBI methods (i.e., the Transient and Steady Simplified methods based on a Beerkan Infiltration run), which allow to estimate K_{fs} by only using a Beerkan experiment.

In terms of drawbacks, BEST methods require collection of supplementary data, e.g., bulk density, particle size distribution. The models also typically fit only transient or steady-state data, but not both. Such peculiarities make it difficult or impossible to apply these methods to heterogeneous datasets, such as the recently developed Soil Water Infiltration Global (SWIG) database (Rahmati et al., 2018). Recently, Stewart and Abou Najm (2018a) developed a new comprehensive model for single ring infiltration data by combining the infiltration models by Reynolds and Elrick (1990) and Wu et al. (1999). These authors proposed four different approaches for estimating K_{fs} values from both transient and steady-state single-ring infiltration data. The four approaches differ in the way they constrain the macroscopic capillary length, λ , and the initial and

81 saturated soil water contents, θ_i and θ_s ; each approach requires different types of input parameters
 82 and exhibits different types and amounts of error. The proposed model has a practical interest in
 83 that it treats both transient and steady-state infiltration data, and can analyze experiments carried out
 84 with different ring sizes and ring insertion depths. However, the model was previously validated
 85 using only laboratory and numerical experiments, meaning that it has not yet been experimentally
 86 validated with field measurements.

87 The objective of this research was to test this new comprehensive model (Stewart and Abou Najm,
 88 2018a) using data acquired for four soils with a range of physical and hydraulic properties. The
 89 model estimated K_{fs} using the four different approaches for constraining λ , θ_i and θ_s , along with
 90 several methods for determining infiltration constants, for a total of thirteen scenarios. The SSBI
 91 method developed by Bagarello et al. (2017) was also applied, giving a fourteenth scenario. The
 92 reliability of K_{fs} estimates were verified first through a comparison with laboratory measurements of
 93 unsaturated hydraulic conductivity, and then via comparison with values obtained by numerical
 94 inverse modeling with HYDRUS-2D/3D.

95 2. Theory

96 2.1. Analysis of single-ring infiltrometer data

97 The model proposed by Stewart and Abou Najm (2018a) describes three dimensional (3D)
 98 cumulative infiltration, I (L), from a surface circular source under a positive pressure head using the
 99 following explicit relationships for transient and steady-state conditions:

$$100 \quad I = \sqrt{\frac{(\theta_s - \theta_i) (h_{source} + \lambda) K_{fs}}{b}} \sqrt{t} + afK_{fs}t \quad t < \tau_{crit}$$

101 (1a)

$$102 \quad I = \frac{(\theta_s - \theta_i) (h_{source} + \lambda) K_{fs}}{4fb(1-a)} + fK_{fs}t \quad t \geq \tau_{crit}$$

103 (1b)

104 where t (T) is the time, τ_{crit} (T) is the maximum time for which the transient relationship can be
 105 considered valid, θ_s (L^3L^{-3}) and θ_i (L^3L^{-3}) are respectively the saturated and initial volumetric soil
 106 water content, h_{source} (L) is the established ponding depth of water, λ (L) is the macroscopic
 107 capillary length of the soil, K_{fs} ($L\ T^{-1}$) is the field-saturated soil hydraulic conductivity, a and b are
 108 dimensionless constants respectively equal to 0.45 and 0.55, and f is a correction factor that depends
 109 on soil initial and boundary conditions and ring geometry (Reynolds and Elrick, 1990):

$$110 \quad f = \frac{h_{source} + \lambda}{G^*} + 1 \quad (2)$$

111 in which the G^* (L) term is equal to:

$$112 \quad G^* = d + \frac{r_d}{2} \quad (3)$$

113 where d (L) is the ring insertion depth into the soil and r_d (L) is the radius of the disk source.

114 Because τ_{crit} is not known a priori, the criterion suggested by Bagarello et al. (1999) can be
 115 considered to discriminate between transient and steady-state conditions for cumulative infiltration
 116 data. Assuming the steady-state conditions are reached before the end of an infiltration run, a linear
 117 regression analysis is conducted for the last three data points of $I(t)$ versus t . The time to steady-
 118 state, t_s (L), is determined as the first value for which:

$$119 \quad \hat{E} = \left| \frac{I(t) - I_{reg}(t)}{I(t)} \right| \times 100 \leq E \quad (4)$$

120 where $I_{reg}(t)$ is estimated from regression analysis, and E defines a given threshold to check
 121 linearity. Equation (4) is applied from the start of the experiment until finding the first data point
 122 that fits the condition $\hat{E} \leq E$ (Angulo-Jaramillo et al., 2016). An illustrative example of t_s
 123 estimation using the commonly used value of $E = 2$ is shown in **Figure 1a**. Transient infiltration
 124 conditions therefore occur from time 0 until time t_s (i.e., when $\hat{E} > 2$; **Figure 1a**), while steady-
 125 state conditions exist for all data points measured after time t_s (i.e., when $\hat{E} \leq 2$).

126 Equations (1) can be simplified as follows (Philip, 1957):

$$I = c_1 \sqrt{t} + c_2 t \quad (5a)$$

$$I = c_3 + c_4 t \quad (5b)$$

where the intercept, c_3 (L), and the slope, c_4 (L T⁻¹), are estimated by linear regression analysis of the $I(t)$ vs. t plot, while the infiltration coefficients c_1 (L T^{-0.5}) and c_2 (L T⁻¹) can be determined according to the fitting methods referred to as cumulative infiltration (CI, e.g. Zhang, 1997), cumulative linearization (CL, Smiles and Knight, 1976) and differential linearization (DL, Vandervaere et al., 1997). In this investigation we considered all three fitting methods, since each method has its own advantages and peculiarities (Vandervaere et al., 2000a). An example of the fitting procedures is depicted in **Figures 1b, c, d**.

2.2. Estimation of field-saturated soil hydraulic conductivity values

Stewart and Abou Najm (2018b) proposed four different approaches, named Approaches 1, 2, 3 and 4, for estimating K_{fs} values from single-ring infiltration data. The differences between the four approaches involve the way in which λ , θ_i and θ_s are constrained, which must occur before estimating K_{fs} . In the following sections, the four approaches are briefly explained.

2.2.1. Approach 1

The first approach estimates K_{fs} by constraining all of the other considered parameters, i.e., λ , θ_i and θ_s , and then fitting Eq. (1) to cumulative infiltration. Stewart and Abou Najm (2018b) proposed to estimate λ from water retention data. Specifically, according to these authors, if the soil is relatively dry at the beginning of the infiltration experiment, λ tends towards a maximum value, λ_{max} (L), defined as:

$$\lambda_{max} = \frac{h_b \eta}{1 - \eta} \quad (6)$$

where η and h_b (L) are respectively the pore size index and the head scale parameter of the Brooks and Corey (1964) relations for water retention and hydraulic conductivity. Note that Eq. (6) can be

150 considered valid for values of the initial matric head of the soil, h_i (L), ranging between $-\infty$ and $2h_b$
 151 (Stewart and Abou Najm, 2018a). Initial and saturated volumetric soil water contents (θ_i and θ_s)
 152 may be measured from soil samples collected before and after the infiltration run or otherwise
 153 estimated.

154 2.2.2.Approach 2

155 Approach 2 only requires estimates for θ_i and θ_s . For transient-state data, once the c_1 and c_2
 156 coefficients are determined, the field-saturated soil hydraulic conductivity and the macroscopic
 157 capillary length are calculated by the following equations:

$$158 \quad K_{fs} = \frac{c_2}{a} - \frac{bc_1^2}{(\theta_s - \theta_i) G^*} \quad (7)$$

$$159 \quad \lambda = \frac{bc_1^2}{K_{fs}(\theta_s - \theta_i)} - h_{source} \quad (8)$$

160 While for steady-state data, K_{fs} and λ are calculated as:

$$161 \quad K_{fs} = \frac{c_4 G^*}{\lambda + h_{source} + G^*} \quad (9)$$

$$162 \quad \lambda = \frac{4c_3b(1-a)(h_{source} + G^*) - h_{source}(\theta_s - \theta_i) G^*}{(\theta_s - \theta_i) G^* - 4c_3b(1-a)} \quad (10)$$

163 2.2.3. Approach 3

164 This approach allows the estimation of the field-saturated soil hydraulic conductivity using only
 165 λ , estimated by Eq. (6), and c_2 or c_4 , as determined from the infiltration run. For transient-state data,
 166 once λ and c_2 are established then the field-saturated soil hydraulic conductivity is calculated by the
 167 following equation:

$$168 \quad K_{fs} = \frac{c_2}{a \left(\frac{h_{source} + \lambda}{G^*} + 1 \right)} \quad (11)$$

169 While for steady-state data, K_{fs} is calculated as:

$$K_{fs} = \frac{c_4}{\left(\frac{h_{source} + \lambda}{G^*} + 1 \right)} \quad (12)$$

2.2.4. Approach 4

Approach 4 uses Eqs. (11) and (12) in conjunction with a λ value of first approximation. Following Stewart and Abou Najm (2018b), a value of $\lambda = 150$ mm was selected for this investigation. This approach does not require additional information to estimate K_{fs} from infiltration runs. Therefore, it is particularly useful when a large number of locations needs to be sampled, particularly when time and financial resources are limited.

2.2.5. SSBI method

For comparative purposes, the SSBI method (Steady-state version of the Simplified method based on a Beerkan Infiltration run) proposed by Bagarello et al. (2017) was also applied to estimate K_{fs} . SSBI estimates K_{fs} through a Beerkan infiltration test, i.e., a simple 3D infiltration run with a quasi-zero water pressure head at the soil surface (Braud et al., 2005; Lassabatere et al., 2006), by the following equation:

$$K_{fs} = \frac{c_4}{\frac{1.364 \lambda}{r_d} + 1} \quad (13)$$

Note that Eq. (13) is analogous to Eq. (16) in Bagarello et al. (2017), with the latter considering the sorptive number, α^* (L^{-1}), which is equal to λ^{-1} (Angulo-Jaramillo et al., 2016). Because Eqs. (12) and (13) are analogous to one another (i.e., both require estimates for c_4 and λ to determine K_{fs}), the SSBI method was also applied assuming $\lambda = 150$ mm.

188 3. Material and methods

189 3.1. Soil Sampling

190 Four soils with contrasting physical and hydraulic properties were evaluated in this study
191 (Castellini et al., 2018). According to the USDA classification, a sandy soil was sampled at Arborea
192 in Sardinia and a silty-loam soil was sampled at the experimental farm of CREA-AA in Foggia,
193 Apulia. Two sandy-loam soils were sampled in Sicily at the Department of Agriculture, Food and
194 Forest Sciences of the Palermo University (sandy-loam 1) and Villabate (sandy-loam 2). For each
195 site, a total 10 undisturbed soil cores (50 mm in height and 50 mm in diameter) were collected at
196 randomly sampled points and used to determine both the soil bulk density, ρ_b (g cm⁻³), and the
197 initial volumetric soil water content, θ_i (cm³cm⁻³). The soil porosity was calculated from the ρ_b data,
198 assuming a soil particle density of 2.65 g cm⁻³. The field saturated soil water content, θ_s (cm³ cm⁻³),
199 was considered equal to the porosity, in line with other studies (e.g., Di Prima et al., 2018d;
200 Mubarak et al., 2009).

201 Disturbed soil samples were also collected to determine the particle size distribution. The
202 samples were air-dried and sieved through a 2-mm mesh. H₂O₂ pretreatment was used to eliminate
203 organic matter and clay deflocculation was encouraged using sodium metaphosphate and
204 mechanical agitation (Gee and Bauder, 1986). Fine size fractions were determined by the
205 hydrometer method, whereas the coarse fractions were obtained by mechanical dry sieving. The soil
206 organic carbon content, SOC (%), was determined by the Walkley–Black method (Walkley and
207 Black, 1934). Then, the soil organic matter content, SOM (%), was estimated using the van
208 Bemmelen conversion factor of 1.724 (Van Bemmelen, 1890). The measured soil physical
209 properties are summarized in **Table 1**. Furthermore, five to nine undisturbed soil cores (85 mm in
210 diameter by 75 mm in height) were also collected at each sampling site to conduct measurements of
211 unsaturated hydraulic conductivity and evaporation tests in the laboratory.

3.2. Laboratory measurements of unsaturated hydraulic conductivity

Laboratory measurements of unsaturated hydraulic conductivity, K_h , were collected to verify the reliability of K_{fs} estimates. We chose to use unsaturated as opposed to saturated conditions as a way to minimize uncertainty due to measurement artifacts such as entrapped air, open-ended pores, and edge flow. All these phenomena can result in considerable variations between field-measured and laboratory-derived estimates of hydraulic conductivity (Di Prima et al., 2018c; Sakaguchi et al., 2005; Stewart and Abou Najm, 2018b). Obviously, the above-mentioned uncertainties are expected to be less noticeable or even negligible for unsaturated measurements. In particular, the comparison between K_{fs} and K_h data allowed us to discriminate between possible ($K_{fs} > K_h$) and physically impossible ($K_{fs} \leq K_h$) situations. The unit hydraulic gradient method (Klute and Dirksen, 1986) was used to determine the unsaturated soil hydraulic conductivity, K_h (mm h^{-1}), on the 85 mm by 75 mm soil cores. According to the procedure described by Bagarello et al. (2007) and Castellini et al. (2015), the upper layer of the soil (≤ 2 mm) was carefully removed to allow the placement of a nylon guard cloth with an air entry value of -160 mm and a thin contact material layer (Spherglass, glass spheres, no. 2227). The nylon guard cloth was also placed at the bottom face of the sample to avoid soil displacement. Each sample was positioned on a sintered porous plate having an air entry value of -400 mm and then connected to an outflow tube that could be moved in height to establish a given pressure head value at the bottom of the core. The sample was previously equilibrated for a 48 h time interval on the porous plate by repeatedly raising the outflow level at the first pressure head value (-120 or -75 mm, depending on the sample). A negative pressure head at the top of the sample, h_0 , was imposed by the tension infiltrometer device, which consisted of a porous disk (85 mm in diameter) connected to the water supply reservoir. Measurements were performed by applying the same pressure head value at the two ends of the soil core. Infiltration evolved from an initial transient stage to a steady-state stage in which a unit hydraulic gradient was obtained (i.e., infiltration rates were constant and pressure head readings were equal throughout the soil core). For

237 this stage, the steady-state flux was equivalent to the unsaturated hydraulic conductivity
238 corresponding to the imposed pressure head value (Bagarello et al., 2007). For the sandy, sandy-
239 loam 1 and sandy-loam 2 samples, the pressure head sequences applied was $h_0 = -120, -60, -30$, and
240 -10 mm, whereas for the silty-loam samples, the sequence was $h_0 = -75, -30$, and -10 mm.

241 3.3. Laboratory evaporation experiments

242 Soil water retention measurements were carried out on the same undisturbed soil cores used to
243 run the unit hydraulic gradient experiments. These experiments allowed us to optimize the
244 parameters of the Brooks and Corey (1964) relationship. In this way, an independent estimate of the
245 macroscopic capillary length (required for Approaches 1 and 3) was determined by inputting the
246 shape, η , and scale, h_b (L), parameters into Eq. (6). In this investigation, we used the evaporation
247 method proposed by Wind (1969) for the computation of the water retention curve, $\theta(h)$, through
248 the simultaneous measurement of volumetric soil water contents and pressure heads at multiple
249 depths during an evaporation process. More details on the laboratory procedure can be found in
250 Castellini et al (2018). The fitting of the water retention data was performed using the program
251 SWRC Fit developed by Seki (2007). This program uses an iterative nonlinear regression procedure
252 that finds the values of the optimized parameters by minimizing the sum of the squared residuals
253 between the model and the observed data. Parameter values are reported in **Table 2**.

254 3.4. Ponding infiltrometer runs

255 For each site, a total of ten ponded infiltration runs of the Beerkan type (Braud et al., 2005;
256 Lassabatere et al., 2006) were carried out at different sampling points. According to the existing
257 literature, the chosen sample size ($N = 10$) was expected to yield representative mean K_{fs} values at
258 the field scale (Reynolds et al., 2000; Verbist et al., 2010). A ring with an inner diameter of 150 mm
259 was used in the Apulian (Foggia, silty-loam) and Sardinian (Arborea, sandy) sites, and a ring with
260 an inner diameter of 85 mm was used in both of the Sicilian sites (sandy-loam 1 and 2). At the

261 Arborea site, a larger ring diameter was chosen due to the presence of a weak but clearly detectable
262 surface structural crust (thickness of ~2 mm), due to the possibility that fractures along the ring
263 edge may connect the ponded surface water with the underlying, non-crust, soil layer
264 (Vandervaere et al., 1997). Beyond the large ring diameter, the small insertion depth (10 mm) used
265 in this study should also help mitigate the formation of fractures through the crusted layer during
266 ring insertion (Alagna et al., 2019; Souza et al., 2014).

267 As prescribed by the Beerkan experimental procedure, the ring was inserted to a depth of 10 mm
268 in all sites. For each run, 15 water volumes, each equal to 64 mL for the 85 mm diameters rings and
269 200 mL for the 150 mm diameter rings, were successively poured on the confined soil surface. The
270 number of infiltrated volumes was sufficient to reach steady-state, as required by the Beerkan
271 method (Lassabatere et al., 2006). The energy of the falling water was dissipated with fingers to
272 minimize the soil disturbance owing to water pouring, as commonly suggested (e.g., Alagna et al.,
273 2016; Bagarello et al., 2014a). For each water volume, the time needed for the water to infiltrate
274 was recorded, and the cumulative infiltration, I (mm) was plotted against time, t (h).

275 **3.5. Numerical Simulation**

276 We chose to use the $K_{fs-HYDRUS}$ values obtained by the inverse procedure in HYDRUS-2D/3D
277 (Šimůnek et al., 2008) as a benchmark, as an independent K_{fs} datum that can be used for assessing
278 simplified procedures or validating new developed methods does not currently exist (Bagarello et
279 al., 2017). As discussed above, laboratory measurements induce experimental artifacts that may
280 limit their comparability with in-situ measurements (Di Prima et al., 2018c). Discrepancies are also
281 expected when different measurement techniques are applied in the field or even when the same
282 dataset is analyzed by alternative calculation approaches (Mertens et al., 2002), though in the latter
283 case the results can still be compared to one another (Wu et al., 1999). The inverse procedure using
284 in HYDRUS-2D/3D combines the Levenberg-Marquardt non-linear parameter optimization method
285 (Marquardt, 1963) with a numerical solution of the axisymmetric form of Richards equation

(Angulo-Jaramillo et al., 2000; Šimůnek and Hopmans, 2002). Similarly to the model configuration used by Stewart and Abou Najm (2018b), the soil columns were modeled as a 2D axisymmetric plane with a depth of 500 mm and a radius of 250 mm. A pressure head boundary condition of 5.7 mm was imposed on the soil surface delimited by the ring, while free drainage was set at the bottom of the modeled domain. The values of θ_r , θ_s , η , and h_b obtained with the evaporation method were used as initial values, to improve the fitting results. Note that the Brooks and Corey models were considered for the water retention and hydraulic conductivity functions, in accordance with the four analytical approaches. The water content parameters θ_r and θ_s were kept fixed and the tortuosity parameter, l , was set to 0.5. Through a least-squares inverse solution routine, η , h_b and $K_{fs-HYDRUS}$ values were optimized using the measured cumulative infiltration data. **Table 3** summarizes the optimized parameters, and an example for each soil of the inverse modeling is depicted in **Figure 2**. For the four sampled soils, $K_{fs-HYDRUS}$ ranged from 28.2 to 839.9 mm h⁻¹. The wide range of $K_{fs-HYDRUS}$ values supported the choice to test the proposed model, and the 14 different scenarios, on these four hydraulically distinct soils.

3.6. Data analysis

In this investigation, we considered a total of 14 different scenarios to estimate K_{fs} data. More specifically, the K_{fs} values were estimated by:

- **Approach 1 (scenario i):** determining λ through Eq. (6) and θ_i and θ_s from sampled soil cores, and then fitting Eq. (1) to cumulative infiltration;
- **Approach 2 (scenarios ii-v):** determining λ , θ_i and θ_s , and introducing the three datasets of c_2 and c_1 values, obtained with the CI, CL and DL fitting methods, into Eqs. (7) and (8), and the c_4 and c_3 values into Eqs. (9) and (10);
- **Approach 3 (scenarios vi-ix):** estimating λ through Eq. (6) and introducing the three datasets of c_2 estimates into Eq. (11), and the c_4 values into Eq. (12);

- **Approach 4 (scenarios x-xiii):** using $\lambda = 150$ mm and introducing the three datasets of c_2 estimates into Eq. (11), and the c_4 values into Eq. (12);
- **SSBI method (scenario xiv)** using $\lambda = 150$ mm and introducing the c_4 values into Eq. (13).

With reference to Approaches 1 and 3, λ values obtained from water retention data and estimated by Eq. (6) were averaged to obtain four site-representative values. A single value of θ_i and θ_s was also obtained for a given site by averaging individual determinations (Approach 1 and 2).

The field-saturated soil hydraulic conductivity, K_{fs} , estimates were compared with the corresponding values obtained by inverse solution from HYDRUS-2D/3D (i.e., the $K_{fs-HYDRUS}$ values) using the relative error, $Er(K_{fs})$, defined as follows:

$$Er(K_{fs}) = 100 \times \frac{K_{fs} - K_{fs-HYDRUS}}{K_{fs-HYDRUS}} \quad (14)$$

Note that positive $Er(K_{fs})$ values indicate overestimations, whereas negative values indicate underestimation. Small deviations, i.e., $Er(K_{fs}) \sim 0$, suggest that the estimates are close to actual values. $Er(K_{fs})$ values between -50% and +100% represent a factor of difference $f_D < 2$ between estimated and actual values. $Er(K_{fs})$ values between -66.7% and +200% represent $f_D < 3$. The factor of difference can be calculated as the ratio between the maximum and minimum of K_{fs} and the corresponding $K_{fs-HYDRUS}$ value [i.e., $f_D = MAX(K_{fs}, K_{fs-HYDRUS})/MIN(K_{fs}, K_{fs-HYDRUS})$]. Following Elrick and Reynolds (1992), f_D values not exceeding a value of two were considered indicative of similar estimates. Also note that all of the estimation and comparison procedures are synthetized in **Figure 2**.

For comparisons between paired observations, the paired differences, i.e., $K_{fs} - K_{fs-HYDRUS}$ for given scenario, were calculated and the hypothesis of normality of these differences was checked by the Kolmogorov-Smirnov test. For normally distributed data, a paired t -test was used to test the mean difference between paired observations at $P < 0.05$. For non-normally distributed data the

334 Wilcoxon signed rank test was used to test the median difference between paired observations at P
 335 < 0.05 .

336 The adequacy of model fits was evaluated by checking the relative error, Er , and the root mean
 337 squared differences, $RMSD$, defined as:

$$338 \quad Er = 100 \times \sqrt{\frac{\sum_{i=1}^n (x_i^{obs} - x_i)^2}{\sum_{i=1}^n (x_i^{obs})^2}} \quad (15)$$

$$339 \quad RMSD = \sqrt{\frac{\sum_{i=1}^n (x_i^{obs} - x_i)^2}{n}} \quad (16)$$

340 where n is the total number of data pairs, x_i^{obs} are the observed data and x_i are the values predicted
 341 by the models. Values of $Er < 5\%$ were assumed indicative of a satisfactory fitting ability of the
 342 models (Angulo-Jaramillo et al., 2016; Lassabatere et al., 2006).

343 **4. Results**

344 In the following subsections we present: i) the results of the analysis of single-ring infiltration
 345 data and the performances of the different fitting methods (section 4.1), ii) the result of the
 346 comparison between K_{fs} data estimated from different scenarios and those values obtained by
 347 numerical inverse modeling with HYDRUS-2D/3D (section 4.2), and iii) a check for data reliability
 348 by comparing K_{fs} estimates with laboratory measurements of unsaturated hydraulic conductivity, K_h
 349 (section 4.3).

350 **4.1. Analysis of single-ring infiltration data**

351 We firstly used Eq. (4) to determine the time to steady-state, t_s , with the condition $\hat{E} > 2$
 352 (**Figure 1a**). This threshold split the experimental data into two subsets that were then fitted to the
 353 transient- ($t < t_s$) and steady-state ($t \geq t_s$) models. Time to steady-state ranged from 1.5–31.1 min,
 354 depending on the run (**Table 4**). For the sandy soil, t_s was on average 19.1 min, with an infiltrated

355 depth $I(t_s)$ of 123.4 mm. In comparison, the sandy loam soils had mean t_s values of 5.2 minutes
356 (sandy-loam 1) and 2.2 minutes (sandy-loam 2). The sandy soil thus required a factor of 4 to 9 more
357 time to reach steady-state conditions compared to the sandy-loam soils, likely due to the presence of
358 a crust layer, which reduced infiltration rates (Alagna et al., 2019, 2013) and affected estimates for
359 infiltration parameters (Di Prima et al., 2018a).

360 During data analysis, peculiarities emerged within some of the infiltration datasets, with three
361 types of abnormal behaviors identified (**Figure 4**). In some runs, the early infiltration rates were
362 particularly high in comparison with the rest of the run (**Figure 4a**), causing a large initial jump in
363 cumulative infiltration (**Figure 4b, white circles**). This circumstance is quite common in coarse or
364 initially dry soils (Di Prima et al., 2016). In this case, the first data point of the $I/\sqrt{t}$ vs. $\sqrt{t}$ plot (CL
365 method) deviated from the general linear behavior (**Figure 4c, white circles**). This problem can be
366 easily solved by excluding the first data point from the cumulative infiltration (**Figure 4b**), allowing
367 the detection of a linear relationship (**Figure 4c, grey circles**), and a proper estimation of the c_1 and
368 c_2 coefficients. Such an adjustment was made on 14 infiltration runs, i.e., 35% of the cases. Other
369 investigations also suggested removing the early stage of the infiltration process when a
370 perturbation occurs (e.g., Bagarello et al., 2014c; Di Prima et al., 2018b; Vandervaere et al., 2000b).

371 One infiltration experiment, from the sandy soil, showed a sudden decrease in infiltration rate
372 (**Figure 4d**). This condition was not easily detectable from the visual inspection of the cumulative
373 infiltration curve (**Figure 4e**), but appeared when the data were linearized (**Figure 4f**). The lack of
374 linear data meant that Eq. (5a) was inappropriate and that the fitted parameters were physically
375 meaningless (Vandervaere et al., 2000a). For this reason the sample was excluded from subsequent
376 analyses. Possible contributing factors include water infiltrating into a less permeable layer (Alagna
377 et al., 2016; Lassabatere et al., 2019), air entrapment, vertical soil water content gradients and soil
378 sealing at the surface from repeated water applications (Bagarello et al., 2014c; Di Prima et al.,
379 2018a).

Other experiments had infiltration rates that increased with time (**Figure 4g**), such that the cumulative infiltration curves exhibited convex shapes (**Figure 4h**). The fitting procedures applied to these data produced negative values for the c_1 infiltration coefficient (**Figure 4i**). These cases occurred at the sandy-loam 1 site (one instance) and sandy-loam 2 site (three instances), and reflect that the early wetting phase was impeded due to hydrophobic surface films on soil particles and non-zero contact angles between water and soil particles (Hallett et al., 2001; Jarvis et al., 2008). Hydrophobia may be attributed to locally high OC content (Goebel et al., 2011) and exudates produced by the plant root systems or living organisms like arbuscular mycorrhizal fungi (Rillig et al., 2010). This effect is known to diminish during the wetting process (Alagna et al., 2018). It should be noted that despite the water repellency, relatively high early infiltration rates were still measured. This result indicates that the soils likely had subcritical water repellency (e.g., Di Prima et al., 2017a; Lassabatere et al., 2019; Lichner et al., 2007; Lozano-Baez et al., 2018).

Three different sets of c_1 and c_2 values were obtained for transient-state data using the CI, CL and DL methods. Overall, the c_1 and c_2 coefficients were properly estimated in 93% of the cases (37 of 40 runs) for the CI and CL methods, and 95% (38 of 40) for the DL method. The c_1 coefficient ranged between 0.4 and 514.3 mm h^{-0.5} and the c_2 coefficient between 95.8 and 4424.2 mm h⁻¹ (**Table 5**). Differences between methods were more pronounced for c_1 compared to c_2 values, with the latter only presenting statistically different estimates between the three procedures for the silty-loam soil (**Figure 5**). Mean c_1 values were ordered as DL > CI > CL. Good fits (i.e., $Er < 5\%$) were obtained for all cases except the DL method on the sandy-loam 2 site (mean $Er = 7.6\%$).

Finally, the analysis of steady-state data (i.e., the data points for which $\hat{E} \leq 2$; Eq. (4)) did not show any such peculiarities, thus, the intercept, c_3 , and the slope, c_4 , of the regression line fitted to the data points describing steady-state conditions could be properly estimated in all cases (**Table 5**).

4.2. Validation with HYDRUS predicted data

The inverse option in HYDRUS-2D/3D was used to optimize the η , h_b and $K_{fs-HYDRUS}$ parameters on the measured cumulative infiltration data. The field-saturated soil hydraulic conductivity, K_{fs} , estimates obtained from the 14 different scenarios were compared with the corresponding values obtained from HYDRUS, i.e., the $K_{fs-HYDRUS}$ values. For Approach 1, site-representative values of λ (**Table 6**), θ_i and θ_s were considered, and K_{fs} was optimized fitting Eq. (1) to cumulative infiltrations. The λ values were obtained by averaging for each soil the individual determination obtained from Eq. (6) and considering the η and h_b parameters optimized on the retention data obtained by the evaporation experiments. The K_{fs} values ranged between 29.2 and 429.1 mm h⁻¹ (**Table 7**), with 45 and 55% of the runs yielding respectively lower and higher K_{fs} estimates than the HYDRUS-estimated values (**Figure 6**). The differences between K_{fs} and $K_{fs-HYDRUS}$ were non-normally distributed according to the Kolmogorov-Smirnov test. The Wilcoxon signed rank test showed that Approach 1 yielded K_{fs} estimates not significantly different from the $K_{fs-HYDRUS}$ values (**Figures 7 and 8**). The relative error, $Er(K_{fs})$, ranged from -66.5 to 347.3%, with mean and median factor of difference, f_D , values equal to 1.45 and 1.22. Individual values f_D were less than two in 85.0% and less than three in 97.5% of the cases, with only one case out of 40 yielding $f_D > 3$ (**Figure 9**). Therefore, K_{fs} estimates were acceptable in almost all cases when Eq. (1) was directly fitted to experimental data.

For Approach 2, four sets of K_{fs} and λ values were determined: three sets for transient infiltration data by Eqs. (12) and (13) (one set for each fitting procedure, i.e., CI, CL and DL), and one set for steady-state data by Eqs. (14) and (15). The three transient scenarios yielded significant higher K_{fs} estimates than the $K_{fs-HYDRUS}$ values (**Figures 7 and 8**), with mean f_D values equal to 12.23 (CI), 16.05 (CL), and 9.30 (DL), and individual f_D values higher than three in 80.0, 92.5 and 72.5% of the cases (**Figure 9**). The steady-state scenario gave negative λ values, and consequentially negative K_{fs} , in 75% of the cases (i.e., 30 out of 40). Overall, Approach 2 either poorly predicted λ and K_{fs}

428 data or failed to give valid estimates at all. The results obtained here can be viewed as a
429 confirmation of the conclusion by Stewart and Abou Najm (2018b).

430 For Approach 3, site-representative values of λ were calculated based on water retention
431 characteristics (**Table 6**) and four sets of K_{fs} values were determined: three sets for transient
432 infiltration data using Eq. (11), and one set for steady-state data using Eq. (12). For these scenarios,
433 K_{fs} ranged between 23.2 and 687.4 mm h⁻¹ (**Table 7**), with the transient scenarios yielding slightly
434 but significantly higher K_{fs} estimates than HYDRUS, and with the steady-state scenarios yielding
435 slightly but significantly lower estimates than HYDRUS (**Figures 7 and 8**). For the four scenarios,
436 f_D values were less than two in at least 75.0% of the transient scenarios and in 95.0% of the steady-
437 state cases (**Figure 9**), with mean f_D values ranging from 1.51 to 1.86 and median f_D values from
438 1.37 to 1.59. Given that K_{fs} estimates were acceptable in all cases, we considered a new scenario
439 (**Figures 6, 7, 8 and 9**) by averaging, for a given run, the four K_{fs} estimates. This newly conceived
440 scenario yielded lower mean and median f_D values, respectively equal to 1.46 and 1.24.

441 For Approach 4, a λ value of 150 mm was used to determine four sets of K_{fs} values (similar to
442 Approach 3). For the transient scenarios, using a λ value of 150 mm resulted in higher K_{fs} values
443 than were predicted by HYDRUS (**Figures 7 and 8**). For these three scenarios, f_D values were
444 higher than two in 67.5-82.5% of the cases and higher than three in 30.0-55.0% of the cases (**Figure**
445 **9**). Mean f_D values ranged from 2.71 to 3.52 and median f_D values varied from 2.59 to 3.27. Better
446 K_{fs} predictions were obtained by the steady-state scenario, with $Er(K_{fs})$ values ranging from -38.6 to
447 460.4%. This scenario yielded slightly but significant higher K_{fs} estimates than the actual values
448 (**Figures 7 and 8**), with mean and median f_D values equal to 1.57 and 1.49. Individual f_D values
449 were respectively less than two and three in 95.0 and 97.5% of the cases, and with only one case out
450 of 40 yielding $f_D > 3$ (**Figure 9**).

451 With the SSBI method, the $Er(K_{fs})$ values ranged from -36.8 to 476.6%, with mean and median
452 f_D values equal to 1.63 and 1.54. Individual values f_D were less than two in 90.0% and less than
453 three in 95.0% of the cases, with only two cases out of 40 yielding $f_D > 3$ (**Figure 9**).

4.3. Unsaturated vs. field-saturated soil hydraulic conductivity

A further check for data reliability was carried out by comparing K_{fs} estimates with laboratory measurements of unsaturated hydraulic conductivity, K_h . **Table 8** summarizes the K_h values measured by the unit hydraulic gradient laboratory method for the four soils. As expected, K_h increased dramatically in the proximity of the saturation, i.e., for lower $|h_0|$ values (**Figure 10**). The mean values of the unsaturated soil hydraulic conductivity obtained at the pressure head $h_0 = -10$ mm (K_{10}) ranged between 21.0 and 154.7 mm h⁻¹, with higher K_{10} values measured on the sandy soil cores.

Firstly, it should be noted that, for the sandy soil, this comparison needs specific consideration owing to crusting phenomena at the soil surface. In particular, the soil core collection process disturbed the crust layer, such that fractures on the soil surface were observed in all soil cores. Therefore, the upper layer of the soil was carefully removed in the laboratory and the measurements of unsaturated hydraulic conductivity were conducted on the underlying, non-crust, soil layer. On the contrary, in the field, we maintained the crust layer during the ponding experiments, in order to give an insight on the potential of the applied model when a layered medium is characterized. As mentioned above, the small insertion depth (i.e., 10 mm) of the ring used to run the Beerkan experiments avoided the formation of fractures in the crust layer, ensuring that the measured infiltration rates were indicative of the crust layer. As a consequence, 9 of 14 scenarios for this soil produced mean values of K_{fs} lower than K_{10} , proving that the soil crust layer reduced water flow during ponding experiments in the field.

For the silty-loam, sandy-loam 1 and sandy-loam 2 soils, K_{fs} determined from the 14 different scenarios always remained higher than the measured K_h values. Therefore, physically possible K_{fs} estimates were obtained in all cases, given that $K_{fs} > K_{10}$. For these soils, the 14 scenarios yielded mean K_{fs} values that were 1.7–68.6 times higher than the corresponding K_{10} , i.e., up to two orders of magnitude. Differences of this order of magnitude or even higher between saturated and near-

479 saturated hydraulic conductivity have been often observed under field conditions (e.g., Buczko et
480 al., 2003; Castellini et al., 2015; Di Prima et al., 2017a; Dunn and Phillips, 1991; Watson and
481 Luxmoore, 1986).

482 5. Discussion

483 The analysis of the cumulative infiltration measurements identified some runs with peculiarities
484 such as very high initial infiltration rates, undetectable linear relationships in the CL and DL
485 methods, and negative values of the infiltration coefficients. Still, infiltration data could be analyzed
486 to determine the constants c_1 and c_2 for 93% of the runs using the cumulative infiltration (CI) and
487 cumulative linearization (CL) methods, and for 95% of the runs using the differential linearization
488 (DL) method.

489 The infiltration constants were next applied to estimate K_{fs} using the comprehensive single-ring
490 infiltration model of Stewart and Abou Najm (2018a). Here, we considered four approaches and
491 thirteen scenarios that differed in how λ was constrained, while also comparing K_{fs} estimates using
492 the SBBI method. Approaches 1 and 3 were the most data demanding, requiring that λ was
493 estimated from water retention data and that soil samples were collected before the infiltration runs
494 to determine initial and saturated volumetric soil water contents (θ_i and θ_s), yet our analysis of the
495 field data showed that those approaches provided the most accurate K_{fs} estimates compared to
496 values obtained through numerical inverse modeling with HYDRUS-2D/3D. Approach 1 was the
497 most accurate overall, likely because it did not require any transformation of the infiltration data.
498 This approach is therefore recommended for situations when λ , θ_i and θ_s are well constrained. Still,
499 by averaging together the four K_{fs} estimates obtained by Approach 3 for a given run (i.e.,
500 considering together the scenarios vi – ix in **Figure 3**), the measurement uncertainty of that
501 approach was reduced to a level comparable to Approach 1. These averaged K_{fs} values avoided
502 uncertainties that might exist within each of the specific fitting procedures (CI, CL and DL), while
503 also overcoming any failed analyses (e.g., negative estimates for K_{fs}). As a result, this newly

504 considered scenario increased the accuracy of K_{fs} estimates, and as a result we recommend users
505 apply a similar averaging scheme when using Approach 3.

506 The K_{fs} estimates were less accurate but still acceptable for the steady-state scenarios of
507 Approach 4 and the SSBI method. The steady-state data likely provided better accuracy than the
508 transient data because the steady phase of the infiltration process avoids uncertainties due to
509 variations in infiltration rates caused by, for instance, soil sealing (Di Prima et al., 2018a) or water
510 repellency (Lichner et al., 2013). With both of these methods, no additional data are required to
511 determine K_{fs} , making these procedures desirable when surveying remote or large areas (Bagarello
512 et al., 2013). One difference between the two is that the SSBI method is theoretically usable for a
513 ponded depth of water on the infiltration surface, h_{source} , equal to zero and a null depth of ring
514 insertion into the soil, d (Bagarello et al., 2017), whereas both zero and positive values of both
515 h_{source} and d can be considered with Approach 4. Here both methods were used to analyze
516 infiltration runs that had a quasi-zero head of water imposed on the soil surface (Beerkan runs), so
517 the models performed similarly to one another.

518 The predictive potential of the model was also checked via comparison with laboratory
519 measurements of unsaturated hydraulic conductivity (K_h). For the silty-loam, sandy-loam 1 and
520 sandy-loam 2 soils, K_{fs} estimates from the 14 different scenarios were always higher than the
521 unsaturated soil hydraulic conductivity. Therefore, physically plausible K_{fs} values were obtained in
522 all cases. For the crusted sandy soil, $K_{fs} < K_h$ situations suggested that the surface crust layer
523 reduced water flow during ponding experiments in the field. In the future, measuring K_h values
524 directly in the field using a tension infiltrometer (Casey and Derby, 2002), or the portable Mini Disk
525 device (Decagon, 2014), may help to properly characterize unsaturated flow in crusted soils.
526 Indeed, field measurements are known to minimize soil disturbance in comparison with laboratory
527 methods performed on collected soil samples (Haverkamp et al., 1999). Moreover, tension
528 infiltrometers were successfully used in many investigations to characterize layered soils in the field
529 (e.g., Alagna et al., 2013; Di Prima et al., 2017b; Šimůnek et al., 1998; Vandervaere et al., 1997).

530 Altogether, the new comprehensive model and the underlying approaches to analyze single-ring
531 data may allow researchers to better approach heterogeneous datasets, including transient or steady-
532 state infiltration data and experiments carried out with different setups. The versatility of the new
533 model makes it a good candidate to successfully analyze the SWIG database developed by Rahmati
534 et al. (2018), which include 5023 infiltration curves collected across the world.

535 **6. Summary and conclusions**

536 In this study, we tested a new comprehensive model for single-ring data on four soils with
537 different textures, i.e., sandy, silty-loam and sandy-loam. The field-saturated soil hydraulic
538 conductivity, K_{fs} , values were estimated by four different approaches, which differ by the way they
539 derive K_{fs} , and constrain λ , θ_i and θ_s . For comparative purposes, the SSBI method was also applied
540 to estimate K_{fs} . In this investigation, we considered a total of 14 different scenarios to estimate K_{fs}
541 data that differed in the considered approach (i.e., Approaches 1-4 or SSBI), in the use of transient
542 or steady-state data, and in the fitting methods applied to transient data (CI, CL and DL).

543 The K_{fs} data estimated from different scenarios were compared for validation purposes with
544 those values obtained by numerical inverse modeling with HYDRUS-2D/3D. Among the different
545 scenarios, Approaches 1 and 3 appear as the more promising, yielding better K_{fs} predictions.
546 Conversely, the steady-state scenario of Approach 4 and the SSBI method are preferable when a
547 simplified experimental procedure is required, such as when sampling remote or large areas, given
548 that these interpretations do not require additional data and still provide acceptable estimates of K_{fs} .

549 **Acknowledgements**

550 This work was supported through the INFILTRON Project (ANR-17-CE04-0010) funded by the
551 French National Research Agency (ANR). S. Di Prima outlined the investigation and analyzed the
552 data. All authors contributed to discussing the results and writing the manuscript.

826

827

828 **Figure 1. (a)** Procedure for estimating the equilibration time, t_s (h), and the infiltrated depth at the
829 equilibration time, $I(t_s)$ (mm), from cumulative infiltrations, and the intercept, c_3 (mm), and slope, c_4
830 (mm h^{-1}), of the regression line fitted to the last data points describing the steady-state conditions on the I
831 vs. t plot. **(b) (c) (d)** Estimation of the c_1 ($\text{mm h}^{-0.5}$) and c_2 (mm h^{-1}) parameters by the cumulative
832 infiltration (CI), cumulative linearization (CL) and differential linearization (DL) fitting methods. The
833 relative error, Er (%) [Eq. (15)], of the fitting of the functional relationships to the experimental data is
834 also reported. The example shows an infiltration run carried out at the silty-loam site.

835 **Figure 2.** Examples of the soil water content profiles at the final time of the experiments (t_{end}) and
836 infiltration curves modeled using the inverse solution from HYDRUS 2D/3D (dashed lines) compared
837 with the observed data (symbols) for the four soils. For each example, the water retention parameters h_b
838 (mm) and η (-), along with the field-saturated soil hydraulic conductivity, $K_{fs-HYDRUS}$ (mm h^{-1}), value
839 obtained by inverse solution from HYDRUS-2D/3D, and the root mean square error, $RMSE$ (mm), and
840 the relative error, Er (%), between the simulated and the observed curves are also reported.

841 **Figure 3.** Flowchart of the fourteen different scenarios and comparison between estimated and HYDRUS-
842 determined values (i.e., K_{fs} vs. $K_{fs-HYDRUS}$).

843 **Figure 4.** Illustrative examples showing three different abnormal behaviors of the infiltration curves.

844 **Figure 5.** Comparison between the mean c_1 ($\text{mm h}^{-0.5}$) and c_2 (mm h^{-1}) parameters estimated by the
845 cumulative infiltration (CI), cumulative linearization (CL) and differential linearization (DL) methods
846 for the four soils (sandy, silty-loam, sandy-loam 1 and sandy-loam 2). The relative error, Er (%), of the
847 fitting of the functional relationships to the experimental data is also reported. For a given variable and
848 soil, different letters represent significant differences according to the Tukey's Honestly Significant
849 Difference test ($P < 0.05$).

850 **Figure 6.** Cumulative empirical frequency distribution of the relative error of the field-saturated soil
851 hydraulic conductivity, $Er(K_{fs})$ [Eq. (14)], predictions (expressed as a percentage of the HYDRUS-
852 determined values, $K_{fs-HYDRUS}$) estimated by: i) Approach 1, ii) averaging individual determinations of the
853 four scenarios considered in the Approach 3, iii) Approach 4 with steady-state data analysis, and iv) the
854 SSBI method.

855 **Figure 7.** Individual value plot of differences between estimated and HYDRUS-determined values (i.e.,
856 $K_{fs} - K_{fs-HYDRUS}$). Gray and black circles indicate datasets that are respectively normally and non-normally
857 distributed according to the Kolmogorov-Smirnov test. Solid circles indicate datasets with a mean
858 (paired t -test) or median (Wilcoxon signed-rank test) difference between pairs not significantly different
859 from zero. Open circles indicate datasets with a mean or median difference between pairs significantly
860 different from zero.

861 **Figure 8.** Comparison between estimated and HYDRUS-determined values (K_{fs} vs. $K_{fs-HYDRUS}$).

862 **Figure 9.** Percentage of infiltration runs yielding a factor of difference, f_D , not exceeding 2, between 2 and 3,
863 and greater than 3, and percentage of failed runs. $f_D = MAX(K_{fs}, K_{fs-HYDRUS})/MIN(K_{fs}, K_{fs-HYDRUS})$.

864 **Figure 10.** Comparison for the four soils (sandy, silty-loam, sandy-loam 1 and sandy-loam 2) between the
865 mean unsaturated soil hydraulic conductivity, K_h (mm h^{-1}), values obtained at different pressure heads, h_0
866 (mm) from the unit hydraulic gradient laboratory method, and the mean field-saturated soil hydraulic
867 conductivity, K_{fs} (mm h^{-1}), values obtained by inverse solution from HYDRUS-2D/3D, the SSBI method,
868 and the four approaches (1, 2, 3 and 4), for different data analysis procedures (transient, Tr., and steady,
869 St.) and fitting methods (cumulative infiltration, CI, cumulative linearization, CL, and differential
870 linearization, DL). For each soil, the vertical list of scenarios reflect the descending order of the K
871 values.

872

Frequency
